Dr Zhang

I write in regards to your Cochrane Review: **Acellular vaccines for preventing whooping cough in children**. (Published online 14 March 2012:
<http://onlinelibrary.wiley.com/doi/10.1002/14651858.CD001478.pub5/full>)

Recently I read a report in The Journal of Infectious Diseases that seems to infer that vaccination is implicated in a whooping cough epidemic in Australia.

Please see below my email to Professor Ruiting Lan, University of New South Wales (an author on the report) on this matter. (Please note I have no expertise in this area, and I may have misinterpreted the information presented in the report.)

Would you be prepared to comment on this subject, i.e. reviewing the queries I present below? I would appreciate your response on this matter, as it may be relevant to your Cochrane Review

Looking forward to your response.

Sincerely
Elizabeth Hart

Professor Lan

I have recently read your JID Brief Report regarding the Australian pertussis epidemic in 2008-2010 (1) which states

"*B. pertussis* isolates collected from 4 Australian states during an ongoing pertussis epidemic that began in 2008 were classified using SNPs, MLVA, *fim3*, *prn*, and *ptxP* typing. SNP cluster 1 strains, primarily SP13 and SP14, accounted for 86% of isolates...This is a significant increase from our previous study of isolates collected between 2000 and 2007, in which SNP cluster 1 represented only 31% of isolates. **This suggests increasing selection among the *B. pertussis* population in Australia in favor of strains carrying antigens that differ from those represented in ACVs.**" (My emphasis.)

and

"**The *prn2-ptxP3* isolates have the potential not only to evade the protective effects of ACV but also to increase disease severity as a double act of *B. pertussis* adaptation. Therefore, vaccine-induced selection could contribute to the expansion of cluster 1**, specifically SP13 and

SP14, because of the presence of both *prn2* and *ptxP3*. These 2 SPs have swept across Australia during the epidemic period. (My emphasis.)

Given these statements, I was confused by your comments in the UNSW website article (2) on this subject, i.e. **"The prolonged whooping cough epidemic in Australia that began during 2008 has been predominantly caused by the new genotype of *B. pertussis*...**The genotype was responsible for 31 percent of cases in the 10 years before the epidemic, and that's now jumped to 84 per cent - a nearly three-fold increase, **indicating it has gained a selective advantage under the current vaccination regime...**The vaccine is still the best way to reduce transmission of the disease and reduce cases, **but it appears to be less effective against the new strain and immunity wanes more rapidly.** We need to look at changes to the vaccine itself **or increase the number of boosters.**" (My emphasis.)

Professor Lan can you please clarify for me how increasing the number of 'boosters' of the existing vaccine protects against the new strain?

Also, how is vaccination "still the best way to reduce transmission of the disease and reduce cases" particularly if "vaccine-induced selection could contribute to the expansion of cluster I"?

I would appreciate your response on this matter.

Yours sincerely
Elizabeth Hart
